

Computing the transition probabilities

- In order to recover transition probabilities $\mathbf{T}(t)$ from the rate matrix \mathbf{Q} , one computes the matrix exponential $\mathbf{T}(t) = \exp(\mathbf{Q}t)$, same as with standard nucleotide models, e.g. HKY85 or GTR.
- Because the computational complexity of matrix exponentiation scales as the cube of the matrix dimension, codon based models require roughly $(61/4)^3 \approx 3500$ more operations than nucleotide models.
- This explains why codon probabilistic models were not introduced until the 1990s, even though they are relatively straightforward extensions of 4x4 nucleotide models

Multiple substitutions

- The model assumes that point mutations alter one nucleotide at a time, hence most of the instantaneous rates:
 - (3134/3761 or 84.2% in the case of the universal genetic code) are 0.
- This restriction, however, does not mean that the model disallows any substitutions that involve multiple nucleotides (e.g., **ACT** \Rightarrow **AGG**).
 - This can be further relaxed with models supporting multiple nucleotide changes.
- Such substitutions must simply be realized via several single nucleotide steps, e.g., **ACT** \Rightarrow **AGT** \Rightarrow **AGG**
- In fact the (i, j) element of $\mathbf{T}(t) = \exp(\mathbf{Q}t)$ sums the probabilities of all such possible pathways of duration t , including reversions
- Compare this to the naive NG86 parsimony approach.
